Abstract. Severe geomagnetic disturbances can be hazardous for modern technological systems. The reliable forecast of parameters related to the state of the magnetosphere can facilitate the mitigation of adverse effects of space weather. This study is devoted to the modeling and forecasting of the evolution of the \( Kp \) index related to global geomagnetic disturbances. Throughout this work the Nonlinear AutoRegressive with eXogenous inputs (NARX) methodology is applied. Two approaches are presented: i) a recursive sliding window approach, and ii) a direct approach. These two approaches are studied separately and are then compared to evaluate their performances. It is shown that the direct approach outperforms the recursive approach, but both tend to produce predictions slightly biased from the true values for low and high disturbances.
1. Introduction

The operation of many modern technological systems is vulnerable to space weather disturbances. Severe geomagnetic disturbances, such as magnetic storms, can have severe adverse effects on power grids, navigation systems and affect satellite drag. Forecasts of space weather hazards can assist reliable operation of these technological systems. However, a physical model of the solar-terrestrial system that can be used to forecast the evolution of the magnetosphere has not been developed yet, because of the complexity of the dynamical processes involved.

The $K_p$ index is one of the most widely used indices for quantifying geomagnetic activity. It stands for *planetarische Kennziffer*, which means planetary index in German. *Thomsen* [2004] concluded that the $K_p$ index is a good measure of the strength of magnetospheric convection because of its dependence on the latitude of the auroral current region. This index is computed by taking the weighted average of K indices at 13 ground magnetic field observatories. The values of $K_p$ range from 0 (very quiet) to 9 (very disturbed) in 28 discrete steps, resulting in values of 0, 0+, 1-, 1, 1+, 2-, 2, 2+, ..., 9 [Wing et al., 2005].

The $K_p$ index is known to be correlated with solar wind observations [Newell et al., 2007; Elliott et al., 2013]. This has enabled the development of models that attempt to forecast $K_p$. The most popular models are...
based on artificial neural networks, which are considered black-box models [Detman and Joselyn, 1999; Boberg et al., 2000]. For instance, in Wing et al. [2005], three neural networks were trained with solar wind data and are now used to nowcast $Kp$ index, producing hourly and 4-hourly forecasts of the $Kp$, updated every 15 minutes. In Bala and Reiff [2012], an improved neural network was trained using the Boyle index in order to generate 1-, 3- and 6-hour ahead predictions. The Liu $Kp$ model consists of a neural network trained with autoregressive values of $Kp$ and solar wind data, and is able to predict $Kp$ values up to 3.5 hours in advance [Liu et al., 2013]. A comparative study between neural networks and support vector machines was done in Ji et al. [2013]. These authors found that the best model is a neural network trained with the same inputs as the Liu $Kp$ model. A probabilistic approach was taken in Wang et al. [2015] where the $Kp$ range is divided in 4 groups and 1268 models were compared in terms of accuracy, reliability, discrimination capability, and forecast skill.

In general, there are two approaches for the modelling of magnetic disturbances. The first one consists of the derivation of a mathematical model that contains comprehensive physical insight into all events and processes that take part in space weather dynamics and disturbances [Wei et al., 2004a]. Such a model can then be used to analyse and forecast future events. Nevertheless, it is obvious that such a model is intractable to ob-
tain given the difficulty to fully describe the intrinsic mechanics. The second is a data-based modelling or system identification approach. System identification is an interesting research area with important applications in science and engineering. It consists in finding a mathematical model from discrete-time observational data in order to characterise the behaviour of a system [Billings, 2013; Wei et al., 2004a].

Since the 1980s, several approaches have been developed in the nonlinear realm of system identification given the fact that most real world problems are nonlinear in nature and conventional linear modelling techniques are not sufficient to characterize nonlinear processes of interest [Pope and Rayner, 1994; Billings, 2013]. One popular approach is the Nonlinear AutoRegressive with eXogenous inputs (NARX) methodology, which has been successfully used to identify nonlinear systems [Billings, 2013; Boaghe et al., 2001; Balikhin et al., 2011]. The NARX approach can detect an appropriate model structure and select the most important model terms from a dictionary consisting of a great number of candidate model terms.

In recent years, several variants have been proposed that improve the performance of the original NARX algorithm. Such variations include the use of more complex and flexible predefined functions such as wavelets [Alexandridis and Zapranis, 2013; Billings and Wei, 2005a, b], radial basis functions [Billings et al., 2007; Wei et al., 2007, 2004a], and ridge basis
functions [Wei et al., 2015], together with an improved search mechanism such as the common model structure selection [Wei and Billings, 2008a; Li et al., 2013, 2015], iterative search [Guo et al., 2015a], incorporation of weak derivatives information [Guo et al., 2015b], and other dependency metrics [Koller and Sahami, 1995; Billings and Wei, 2007; Wei and Billings, 2008b; Wang et al., 2013; Speed, 2011; Reshef et al., 2011; Székely et al., 2007; Székely and Rizzo, 2013; Piroddi and Spinelli, 2003; Ayala Solares and Wei, 2015].

The NARX approach produces transparent and interpretable models in which the contribution of each model term to the output signal can be evaluated. This methodology has been previously used to model space weather phenomena. For example, it was used to model the evolution of energetic electrons fluxes at geostationary orbit [Balikhin et al., 2011], to obtain the most influential coupling functions that affect the evolution of the magnetosphere [Boynton et al., 2011], to predict the Dst index using multiresolution wavelet models [Wei et al., 2004a], to build a multiscale radial basis function network to forecast the geomagnetic activity of the Dst index [Wei et al., 2007], and to unravel the time varying relationship between the solar wind and the SYM-H index [Beharrell and Honary, 2016], among others. Furthermore, NARX models can be used to compute the generalized frequency response functions (GFRFs) in order to perform frequency domain
analysis [Billings, 2013]. This technique has been used previously to study the spectral properties of the Dst index dynamics [Balikhin et al., 2001] and to identify types of nonlinearities involved in the energy storage process in the magnetosphere [Boaghe et al., 2001].

In this paper we investigate the use of NARX models to forecast the Kp index. In particular we are interested in forecasts at four different horizons: 3, 6, 12 and 24 hours ahead. To do so, we explore two approaches. The first one consists of a recursive sliding window scheme in which we employ a window period of 6 months to train a model and use it to forecast future values based on previous predictions. The second approach involves the identification of a specific model for each horizon of interest using a fixed dataset of 6 months.

This paper is organised as follows. Section 2 contains a brief summary of the nonlinear system identification methodology, together with a discussion of the Orthogonal Forward Regression algorithm. In section 3 the dataset used for the analysis is described. The NARX recursive approach is developed in section 4, while section 5 is dedicated to the direct approach. Section 6 compares both approaches. The work is concluded in section 7.

2. Nonlinear System Identification

The aim of the system identification modelling approach is to find a model from observational data that can capture as close as possible the relation-
ship between a system input and output [Söderström and Stoica, 1989; Billings, 2013]. Linear system identification has been a popular, widely used approach. Nevertheless, the high complexity of most real-life systems compromise the linearity assumption [Pope and Rayner, 1994]. To overcome this issue, several studies have been performed in the nonlinear realm [Billings, 2013]. In particular, the Nonlinear AutoRegressive with eXogenous inputs (NARX) methodology has become a powerful tool for nonlinear system identification problems [Billings, 2013; Wei et al., 2004a, b; Rashid et al., 2012].

Model structure detection is a challenging task in dynamic system identification. This topic has been studied extensively and a vast amount of information can be found in the literature. Model structure detection has been tackled using different methods, such as clustering [Aguirre and Jácôme, 1998; Feil et al., 2004], the Least Absolute Shrinkage and Selection Operator (LASSO) [Kukreja et al., 2006; Qin et al., 2012], elastic nets [Zou and Hastie, 2005; Hong and Chen, 2012], genetic programming [Sette and Boullart, 2001; Madár et al., 2005], the Orthogonal Forward Regression (OFR) using the Error Reduction Ratio (ERR) approach [Wei et al., 2004b], and the bagging methodology [Ayala Solares and Wei, 2015]. The second step is parameter estimation, which is typically performed using the traditional least squares method, gradient descent and the Metropolis-Hastings
algorithm [Baldacchino et al., 2012; Teixeira and Aguirre, 2011]. The final step is model validation, for which several authors have developed different approaches. In Billings and Voon [1986], a set of statistical correlation tests have been developed that can be used for validation of a nonlinear input-output model.

2.1. Appropriate Model Term Selection

Consider the NARX model:

\[ y(k) = f(y(k - 1), \ldots, y(k - n_y), u(k - 1), \ldots, u(k - n_u)) + e(k) \]  

(1)

where \( f(\cdot) \) is a function to be determined from data, \( u(k) \) and \( y(k) \) are the system input and output signal respectively, \( e(k) \) is system noise (with \( k = 1, 2, \ldots, N \)), and the maximum lags for the input and output signals are \( n_u \) and \( n_y \) [Wei and Billings, 2008b]. Most approaches assume that the function \( f(\cdot) \) can be approximated by a linear combination of a predefined set of functions \( \phi_i(\varphi(k)) \), therefore equation (1) can be expressed in a linear-in-the-parameters form

\[ y(k) = \sum_{i=1}^{M} \theta_i \phi_i(\varphi(k)) + e(k) \]  

(2)

where \( \theta_i \) are the coefficients to be estimated, \( \phi_i(\varphi(k)) \) are the predefined functions that depend on the regressor vector \( \varphi(k) = \)
\[
\left[ y(k-1), \ldots, y(k-n_y), u(k-1), \ldots, u(k-n_u) \right]^T
\]

of past outputs and inputs, and \( M \) is the number of functions in the set.

The most popular algorithm for NARX modelling is the Orthogonal Forward Regression (OFR) algorithm \cite{Guo2015,Billings2013}. OFR is a stepwise algorithm \cite{Billings1989}, which follows a recursive-partitioning procedures \cite{Dietterich2002} to identify a parsimonious NARX model \cite{Wei2008,Biggerstaff2009}. One of the most commonly used NARX models is the polynomial NARX representation, where equation (2) can be written as

\[
y(k) = \theta_0 + \sum_{i_1=1}^{n} \sum_{i_2=1}^{n} \ldots \sum_{i_\ell=1}^{n} \theta_{i_1i_2\ldots i_\ell} x_{i_1}(k) x_{i_2}(k) \ldots x_{i_\ell}(k) + e(k)
\]

where

\[
x_m(k) = \begin{cases} y(k-m) & 1 \leq m \leq n_y \\ u(k-m+n_y) & n_y + 1 \leq m \leq n = n_y + n_u \end{cases}
\]

and \( \ell \) is the nonlinear degree of the model. A NARX model of order \( \ell \) means that the order of each term in the model is not higher than \( \ell \). The total number of potential terms in a polynomial NARX model is given by

\[
M = \binom{n+\ell}{\ell} = \frac{(n+\ell)!}{n! \cdot \ell!}
\]
The OFR algorithm performs a stepwise regression procedure to identify the most significant model terms. To achieve this, it uses the Error Reduction Ratio (ERR) index to measure the significance of each candidate model term [Billings, 2013]. This index can be evaluated by calculating the normalised energy coefficient $C(x, y)$ between two associated vectors $x$ and $y$ [Billings and Wei, 2007]

$$C(x, y) = \frac{(x^T y)^2}{(x^T x)(y^T y)}$$ (6)

In recent years, several variants of the algorithm have been proposed that modify the predefined functions, the dependency metric or the search mechanism in order to enhance its performance. In particular, the ERR index only detects linear dependencies; so new metrics have been proposed to capture nonlinear dependencies [Billings and Wei, 2007; Wei and Billings, 2008b], i.e. entropy, mutual information [Koller and Sahami, 1995; Billings and Wei, 2007; Wei and Billings, 2008b; Wang et al., 2013], simulation error [Piroddi and Spinelli, 2003] and distance correlation [Ayala Solares and Wei, 2015].

Most of these variants are able to obtain good one-step ahead (OSA) predictions,
\[
\hat{y}(k) = f\left( y(k-1), y(k-2), \ldots, y(k-n_y), u(k-1), u(k-2), \ldots, u(k-n_u) \right)
\]  
(7)

However, because the NARX model (1) depends on past outputs, a more reliable way to check the validity of the model is through the model predicted output (MPO), which uses past predicted outputs to estimate future ones, and to provide details about the stability and predictability range of the model,

\[
\hat{y}(k) = f\left( \hat{y}(k-1), \hat{y}(k-2), \ldots, \hat{y}(k-n_y), u(k-1), u(k-2), \ldots, u(k-n_u) \right)
\]  
(8)

In the literature, some authors have adapted the original OFR algorithm to optimize directly the MPO in order to obtain a better long-term prediction. However these modified versions tend to be computationally expensive during the feature selection step, and a much better alternative is to use the iterative or ultra-orthogonalisation approach [Guo et al., 2015a, b].

Furthermore, in many real applications, multiple step-ahead predictions are of interest. For an autonomous system (e.g. a time series process without external input), the system output value at the current time instant \(k\), i.e. \(y(k)\), may be predicted using previous observations at time instants \(k-s, k-s-1, \ldots\), and the predicted value \(\hat{y}(k)\) is called the \(s\)-step.
ahead prediction. For an input-output system, the $s$-step ahead prediction $\hat{y}(k)$ is often estimated using previous output measurements $y(k - s), y(k - s - 1), \ldots$, and previous input values $u(k - 1), u(k - 2), \ldots$, etc. So, for an input-output system model, the $s$-step ahead prediction is defined with respect to the system output; it is actually still one-step ahead prediction with respect to the system input.

3. Dataset description

Every three hours throughout the day, 13 ground-based magnetic field observatories located at geomagnetic latitudes between 48° and 63° around the world, record the largest magnetic change that their instruments measure. This change is denoted as the $K$ index, which is given on a quasi-logarithmic scale from 0 ($< 5nT$) to 9 ($> 500nT$) [Boberg et al., 2000]. The average of these observations is known as the $Kp$ index. This determines how disturbed the Earth’s magnetosphere is on a scale that goes from 0 (very quiet) to 9 (very disturbed) in 28 discrete steps, resulting in values of 0, 0+, 1-, 1+, 2-, 2, 2+, ..., 9 [Boberg et al., 2000; Wing et al., 2005]. In this paper, these values are rescaled to be represented by the numbers 0, 0.3, 0.7, 1, ..., 9.

In general, large $Kp$ values can indicate a more active terrestrial magnetosphere due to a solar storm, or a sudden rearrangement of the Earth’s magnetosphere due to the solar wind.
The datasets used in this paper consist of the variables shown in Table 1. These were measured during the year 2000. The inputs are taken from the low resolution OMNI dataset, which consist of hourly average near-Earth solar wind magnetic field and plasma data from several spacecraft in geocentric or L1 (Lagrange point) orbits. The data period used for this study employed four spacecraft: IMP 8, WIND, Geotail and ACE. The output is the $K_p$ index which, as mentioned before, is measured every three hours. In order to match the time resolutions between the input and output signals, the observed $K_p$ values are interpolated to 1-hour resolution by simply repeating the last measured value during the next two hours.

Given that the variable of interest is the $K_p$ index, its distribution for year 2000 is shown in Fig. 1. This highlights that high values of $K_p$ are rare, which makes their prediction a challenging task.

4. Sliding Window Models and Recursive Predictions

This approach uses a window of a fixed length to build a single model using the data within the window frame as the training set. This model is used to make 3-, 6-, 12- and 24-hour ahead predictions based on the model simulated values (i.e. the model predicted outputs - MPOs) as shown in equation (8). Once this is done, the window is moved forward by one time step, a new model is built and subsequently used to forecast the next 3-,
6-, 12- and 24-hour ahead $Kp$ values. This way, the training and validation sets are mutually exclusive.

Every time the window frame moves forward, a new NARX model is trained. The training process uses the adaptive orthogonal search algorithm described in Billings and Wei [2008]. A nonlinear model term and variable selection procedure proposed in Wei et al. [2004b] was applied, and numerical experimental results suggested that $n_u = 4$ and $n_u = 2$ was an appropriate choice. Accordingly, the NARX model structure is given by

$$\hat{Kp}(k) = \hat{f}\left( Kp(k-1), \ldots, Kp(k-4), V(k-1), V(k-2), Bs(k-1), Bs(k-2), V Bs(k-1), V Bs(k-2), p(k-1), p(k-2), \sqrt{p(k-1)}, \sqrt{p(k-2)} \right)$$

(9)

where $f(\cdot)$ is chosen to be a polynomial of nonlinear degree $\ell = 2$, $Kp(k)$ is the measured $Kp$ index at time $k$, and $\hat{Kp}(k)$ is the predicted $Kp$ index at time $k$. In our analysis, the window length is of 6 months, therefore the initial training and validation sets correspond to the first and second half of year 2000, respectively. As the window frame moves forward, the validation set size decreases. The reason to choose a window length of 6 months is because for the NARX methodology typically just a few hundred data samples are required to estimate a model, which can be important.
in many applications where it is unrealistic to perform long experiments [Billings, 2013].

The results for this approach are shown in Fig. 2. Here it can be seen that there is a bias for low and high magnetic disturbances. Furthermore, for high values of $K_p$ ($K_p \geq 8$) the error bars become odd and difficult to interpret. This is due to the fact that there are very few occurrences of high-value $K_p$ indexes, so few predictions are made in such cases and hence they tend to be underpredicted. Such characteristics have been previously reported in Detman and Joselyn [1999]; Boberg et al. [2000], where it is argued that a model will perform well for the most common training values, while predictions for others will be poor.

To quantify our results, the root mean squared error (RMSE), correlation coefficient ($\rho$) and prediction efficiency (PE) are computed. The latter is defined as

$$PE = 1 - \frac{\sigma^2_{error}}{\sigma^2_{measured}}$$  \hspace{1cm} (10)

where $\sigma^2_{measured}$ is the variance of the measured $K_p$ values, and $\sigma^2_{error}$ is the variance of the error between the measured $K_p$ values and the predicted ones. These metrics are shown in Table 2.

The error time series for each of the four horizons of interest are shown in Fig. 3. It can be seen that the error is notoriously high at the middle of
July. Fig. 4 shows a glimpse of this period where it can be seen that high activity of the terrestrial magnetosphere was recorded between July 13th-17th, 2000. Such an activity was not properly forecasted by this approach. In addition, Table 3 shows a statistical summary of the error time series in Fig. 3. In general, it can be concluded that this approach tends to overpredict the $Kp$ index given that both the median and the mean are negative. Furthermore, as the number of hours to predict ahead increases, the forecasts are less accurate because the interquartile range (1st quartile - 3rd quartile) increases.

5. Direct approach

The second modelling technique investigated in this paper involves use of what is termed the direct approach. Instead of training a model many times and using it recursively to calculate forecasts, the direct approach obtains a separate model for a horizon $h$ of interest. In such a case, equation (1) becomes

$$y(k) = f\left(y(k - h), y(k - h - 1), \ldots, y(k - h - n_y), u(k - 1), u(k - 2), \ldots, u(k - n_u)\right) + e(k)$$

The main advantage of the direct approach is that it only requires the computation of $h$-step-ahead predictions. This means that the output at the present time $k$, $y(k)$, is predicted using the past values $y(k - h)$,
\[ y(k - h - 1), \ldots, y(k - h - n_y), u(k - 1), u(k - 2), \ldots, u(k - n_u), \]
where it is assumed that these are known [Wei et al., 2007].

In similarity to the sliding window approach, \( n_y = 4 \) and \( n_u = 2 \) were chosen, and the training process uses the adaptive orthogonal search algorithm described in Billings and Wei [2008]. Accordingly, the NARX model structure is given by

\[
\hat{K}_p(k) = f\left( K_p(k-h), \ldots, K_p(k-h-3), \right.
\]
\[
V(k-1), V(k-2), B_s(k-1), B_s(k-2),
\]
\[
V B_s(k-1), V B_s(k-2), p(k-1), p(k-2),
\]
\[
\sqrt{p(k-1)}, \sqrt{p(k-2)} \right)
\]

(11)

where \( f(\cdot) \) is chosen to be a polynomial of nonlinear degree \( \ell = 2 \), \( K_p(k) \) is the measured \( K_p \) index at time \( k \), and \( \hat{K}_p(k) \) is the predicted \( K_p \) index at time \( k \). In this analysis, the first six months of year 2000 are used for training while the second half of the year is used for validation.

The models identified by the NARX methodology for each horizon are listed below:

- 3-hours ahead
$$\tilde{K}_p(k) = 0.325543K_p(k-3) - 0.000043V(k-1)\sqrt{p(k-1)} + 0.673034Bs(k-1)$$

$$- 0.164093Bs(k-1)\sqrt{p(k-1)} - 0.000003V(k-1)^2 + 0.000217V(k-1) \cdot Bs(k-2)$$

$$- 0.006701Bs(k-1) \cdot Bs(k-2) - 0.005810Bs(k-1) \cdot p(k-2) - 2.179360$$

$$+ 0.753122\sqrt{p(k-1)} + 0.006105V(k-1) - 0.387292VBs(k-1)$$

$$+ 0.136271VBs(k-1)\sqrt{p(k-1)}$$

(12)

- 6-hours ahead

$$\tilde{K}_p(k) = - 0.000191V(k-1)\sqrt{p(k-1)} + 0.852464Bs(k-1) + 0.158716K_p(k-6)$$

$$- 0.172607Bs(k-1)\sqrt{p(k-1)} + 0.000340V(k-1) \cdot Bs(k-2) - 0.000003V(k-1)^2$$

$$- 0.058229Bs(k-1) \cdot Bs(k-2) - 0.007989Bs(k-1) \cdot p(k-2)$$

$$+ 0.009495\sqrt{p(k-1)}\sqrt{p(k-2)} + 0.000962p(k-1) \cdot p(k-2) - 2.749889$$

$$+ 0.007744V(k-1) + 0.958020\sqrt{p(k-1)} - 0.514336VBs(k-1)$$

$$+ 0.113874VBs(k-1)\sqrt{p(k-1)} + 0.011219VBs(k-1)^2 + 0.009277VBs(k-2)^2$$

$$+ 0.032255Bs(k-2) \cdot V Bs(k-1)$$

(13)

- 12-hours ahead

\[ K_p(k) = 0.001618V(k - 1)\sqrt{p(k - 1)} + 0.748665Bs(k - 1) - 0.268901Bs(k - 1)\sqrt{p(k - 1)} \]
\[ - 0.000229K_p(k - 12) \cdot V(k - 1) + 0.203764Bs(k - 2) - 0.017656K_p(k - 12) \cdot p(k - 1) \]
\[ - 0.007676Bs(k - 1) \cdot Bs(k - 2) - 1.606480 - 0.000324V(k - 1) \cdot p(k - 1) \]
\[ - 0.003098K_p(k - 12) \cdot V Bs(k - 1) + 0.286045p(k - 1) - 0.012219K_p(k - 12) \cdot V Bs(k - 2) \]
\[ - 0.531734V Bs(k - 1) + 0.195865V Bs(k - 1)\sqrt{p(k - 1)} \quad (14) \]

24-hours ahead

\[ \hat{K}_p(k) = 0.000066V(k - 1)\sqrt{p(k - 1)} + 0.838922Bs(k - 1) - 0.213375Bs(k - 1)\sqrt{p(k - 1)} \]
\[ + 0.011558K_p(k - 24) \cdot Bs(k - 2) - 0.000004V(k - 1)^2 + 0.269300Bs(k - 2) \]
\[ - 0.066312Bs(k - 1) \cdot Bs(k - 2) - 3.080364 + 1.023429\sqrt{p(k - 1)} \]
\[ + 0.008776V(k - 1) + 0.014446Bs(k - 1)^2 - 0.573961V Bs(k - 1) \]
\[ + 0.120880V Bs(k - 1)\sqrt{p(k - 1)} + 0.007968K_p(k - 25)^2 + 0.012127Bs(k - 2)^2 \]
\[ + 0.034862V Bs(k - 1) \cdot V Bs(k - 2) - 0.121102V Bs(k - 2) \]
\[ + 0.000240V(k - 2) \cdot V Bs(k - 1) \quad (15) \]

The results of this approach are shown in Fig. 5. They display a similar pattern to the sliding window approach, i.e. there is a bias for low and high magnetic disturbances, and the error bars for high values of \( K_p \) (\( K_p \geq 8 \)).

©2016 American Geophysical Union. All Rights Reserved.
become less meaningful. Once again, these characteristics are due to the
uncommon number of cases of high values of the $Kp$ index compared with
the most common $Kp$ values related with quiet activity periods of the
magnetosphere.

To quantify our results, the root mean squared error (RMSE), correlation
coefficient ($\rho$) and prediction efficiency (PE) are computed. These metrics
are shown in Table 4.

The error for each of the four horizons of interest is respectively shown in
Fig. 6: Once again, there is a notoriously high error at the middle of July,
corresponding to a period of high geomagnetic activity, as mentioned above.

A glimpse of this period is shown in Fig. 7. In addition, Table 5 shows a
statistical summary of the error time series in Fig. 6. In general, it can be
concluded that on average, this approach tends to slightly underpredict the
$Kp$ index given that the means are positive. Furthermore, as the number
of hours to predict ahead increases, the forecasts are less accurate because
the interquartile range (1st quartile - 3rd quartile) increases, as expected.

6. Model Comparison

A quick view to Tables 3 and 5 shows that the direct approach provides
better forecasts than the sliding window approach because the means and
medians are closer to zero, and the interquartile ranges are smaller. To
better visualise this difference, a randomly selected 30-day interval on the
second half of year 2000 is taken. The features dynamics are shown in Fig. 8.

The model forecasts using both approaches during this 30-day interval are shown in Figs. 9-10.

To quantify our results, the root mean squared error (RMSE), correlation coefficient (\(\rho\)) and prediction efficiency (PE) are computed. These metrics are shown in Table 6.

These results show that better forecast accuracy is obtained by the direct approach. This is an expected result given that the sliding window approach uses model predicted outputs from a single model, and long-term forecasts tend to deviate from true values as time goes on. On the other hand, the direct approach uses a separate model for each horizon and relies on single calculations for \(h\)-step-ahead predictions. However, both approaches show that predictions for low and high disturbances are slightly biased from the true values. This observation is coincident with previous findings reported in Detman and Joselyn [1999] and Boberg et al. [2000], where a model will perform well for the most common training values, while predictions for others will be poor. Another explanation is that this comes as a trade-off for using a regression model to predict a categorical output variable.

Comparing the results obtained with those presented in Wing et al. [2005], the values of the two model performance metrics (i.e. prediction perfor-
mance and correlation coefficient) calculated from our results are slightly lower. This may be explained from several factors: i) all the data for all input and output variables used for model estimation in this study are raw data sampled hourly where no pre-processing (e.g. smoothing, interpretation, etc.) was performed; ii) the model input variables used in this work are not exactly the same as those used in previous studies; iii) some coefficients required by the models, for example the maximum lags of the input and output variables, may need to be optimised further. Note that one of the objectives of this work is to generate compact transparent models to show how $K_p$ index depends on solar wind parameters and geomagnetic field indices, and then use such models to do further analysis including forecast. As shown in models 12-15, an important contribution obtained from the direct approach is that there are three significant model terms that are shared by all the models. These are shown in bold in the equations above. The values of the three terms, together with the $K_p$ index, are normalised, and the associated scatter plots are shown in Fig. 11 (note that the normalisation of the values is just to facilitate the visualisation and comparison of the scatter plots). The importance of the first selected common model term $V(k-1)\sqrt{p(k-1)}$ may be roughly explained by its relevance with $K_p$ when measuring the correlation coefficient ($\rho = 0.6149$). Model terms
ranked later would normally not be so important as the top ones, and their correlation with the $Kp$ signal becomes very weak.

The importance of the model terms selected in the equations above is not always measured by the values or amplitude of these model terms. A model term with a high (or low) value does not necessarily mean a high (or low) value in $Kp$ index, as its change is an outcome of combined and weighted interactions of many lagged input variables. Experience shows that top model terms can reflect the major varying trend of the output signals, while model terms ranked later can be useful in revealing local and relatively minor changes. While the role of solar wind speed and dynamic pressure as drivers of the $Kp$ index has been confirmed by previous studies, this work provides some further information with an explicit format of these input variables, showing what kind of interactions of these drivers make a contribution to the change of the $Kp$ index. This is important for further understanding and analysis of the dependent relationship of the $Kp$ index on solar wind speed and dynamic pressure, etc.

7. Conclusion

In this paper, we have applied the NARX modelling methodology to the forecasting of the $Kp$ index. We have obtained a number of models using two different implementation approaches: namely, recursive prediction approach based on sliding windows and a direct approach which can di-
rectly generate $h$-hour ahead predictions ($h = 3, 6, 12$ and $24$ in our case studies). In general, good forecasts were obtained for both short and long-term prediction using the estimated NARX models, but the direct approach outperforms the recursive approach. Nevertheless, both approaches tend to show that predictions for low and high disturbances are slightly biased from the true values. As previously reported, such a bias is a result of the uneven distribution in the output signal, and in this paper, the use of a regression model to predict a categorical output variable may also play a role on this matter. An interesting property obtained from the direct approach is a set of significant model terms that are shared by all the models, regardless of the time horizon of interest. While the role of the solar wind speed and dynamic pressure as drivers of the $K_p$ index has been confirmed by previous studies, the present work produced some further information showing the relative contributions made by these drivers to the changes in the $K_p$ index. This is useful for further understanding the relationship of the $K_p$ index to solar wind. It was noticed that the values of prediction performance and correlation coefficient relating to our models are slightly lower than those reported by Wing et al. [2005] and possible reasons were briefly discussed. To improve the overall performance of the proposed models, the following investigations will be considered: i) in dynamic regression modeling, the choice of maximum lags for both input and output variables is
important, therefore it is highly desirable to introduce an adaptive maximum lag selection scheme to accommodate the non-stationary features of both the input and output sequences; ii) the raw $K_p$ data are categorical, the recently developed logistic-NARX model may be more appropriate to deal with the $K_p$ prediction problem where the output signal is categorical while the input variables are time-continuous.

8. Acknowledgement

The authors acknowledge the financial support to J. R. Ayala Solares from the University of Sheffield and the Mexican National Council of Science and Technology (CONACYT). The authors gratefully acknowledge that part of this work was supported by the Engineering and Physical Sciences Research Council (EPSRC) under Grant EP/I011056/1 and Platform Grant EP/H00453X/1, and EU Horizon 2020 Research and Innovation Programme Action Framework under grant agreement No 637302.

The authors would like to thank Professor Michael Balikhin for his constructive comments and suggestions for improving the paper. The solar wind and $K_p$ index data were provided by the OMNIWeb Service (http://omniweb.gsfc.nasa.gov), which is gratefully acknowledged.

Plots and numerical results of the paper are available from the author on request; more results will be available from a publicly accessible website later.
